FINGERPRINTING TO REDUCE RISKY BORROWING

Introducing fingerprinting identification for microloans caused high-risk borrowers to take out smaller loans and to improve their repayment behavior.

Formal banks rarely serve the rural poor. Microfinance has filled part of this gap, but lenders' ability to keep costs low and continue extending credit to the poor depends in part on their ability to encourage repayment from borrowers who typically lack adequate collateral or verifiable credit histories. Lenders may use "dynamic incentives," such as the promise of larger loans or the threat of future credit denial, to elicit timely repayment and lower lending costs.

These dynamic incentives, however, work only when borrowers can be consistently identified. In countries lacking formal identification systems, borrowers may avoid sanction for past default by simply applying for new loans under different identities or from different institutions. This can raise the cost of lending by allowing for more default, and the response of many lenders has been to limit the supply of credit and increase its price, which affects many creditworthy smallholder farmers who cannot finance crucial inputs such as fertilizer and improved seeds.

Can biometric identification technology, such as fingerprinting, encourage borrowers to repay their loans and enable financial institutions to grant more loans to creditworthy applicants, reducing the costs and risks of lending? Researchers Xavier Giné (World Bank), Jessica Goldberg (U. Michigan), and J-PAL affiliate Dean Yang (U. Michigan) implemented a randomized evaluation to test this question. The evaluation introduced a fingerprinting system among randomly selected smallholder paprika farmers receiving microfinance loans for subsidized farming inputs in Malawi. Researchers then measured whether borrowing behavior, such as loan repayment rates, changed in response to the identification system.
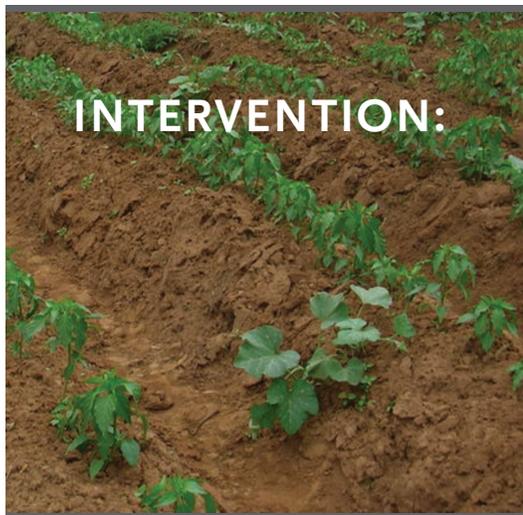

- **Fingerprinting improved the credibility of the lender's dynamic incentives, without deterring borrowers from seeking credit.** Lenders were better able to identify borrowers, enabling them to construct accurate credit histories for clients, and potentially to withhold loans from past defaulters and reward timely repayment with expanded credit. Borrowers did not take out fewer loans when biometric identification was introduced, but they were somewhat more cautious, borrowing less money overall.

- **Fingerprinting improved repayment rates, particularly for borrowers with the highest default risk.** The program influenced farmers' behavior at both the application stage and the repayment stage. The riskiest borrowers voluntarily reduced their loan size and allocated more subsidized inputs and more land to crops which would be used for repayment. Farmers who had been fingerprinted were also less likely to default on their loans.

- **Using biometric technology to identify borrowers had a high rate of return for the lender.** The improved loan repayments more than compensated the lender for the costs of implementing the fingerprinting system. The researchers estimate a net benefit to the lender of MWK 281 (US$1.94) per individual fingerprinted.

The evaluation took place in Malawi, where rural areas are home to over 85 percent of the country's population and 80 percent of its small and micro-enterprises. Agriculture accounts for more than one-third of Malawi's GDP and 90 percent of exports. Access to credit for smallholder farmers is limited. At the time of the study, the vast majority of farmers in the sample had no access to formal-sector credit, and only 7 percent had any formal loans in the previous year.

In response to this need, the Malawi Rural Finance Corporation (MRFC), a government-owned microfinance institution, provides loan products designed for rural farmers. Paprika farmers can take out loans for "starter kits" from Cheetah Paprika Limited (CP), a private agri-business that offers extension services and a subsidized package of high-quality inputs (seeds, pesticides, fungicides, and fertilizer) in exchange for farmers' commitment to sell the paprika crop to CP at harvest time. The loan package offered did not include cash to purchase inputs. Instead, borrowers took a voucher from MRFC to a pre-approved supplier, who provided the input package to the farmer and billed MRFC. The average loan value was MWK 16,913 (US$117), and expected yield from using the full input package on one acre of land was 400-600 kg, double or triple the expected 200 kg yield with no inputs.

Researchers collaborated with MRFC and CP to evaluate the impact of implementing a fingerprinting system to identify borrowers who applied for loans from MRFC. More than 3,000 farmers who applied for agricultural input loans to grow paprika were randomly assigned to either a comparison group or a treatment group. Both groups were given a presentation on the importance of credit history in ensuring future access to credit.

INTERVENTION:

Fingerprinting ➡

In the treatment group, each farmer had a fingerprint collected as part of the loan application. An explanation was given that the fingerprint would be used to identify them on any future loan applications, and the farmers participated in a demonstration where a computer identified one of their peers with a fingerprint scan.

During July and August of 2008, farmers harvested the paprika crop and sold it to CP at predefined collection points. CP then transferred the proceeds from the sale to MRFC, who deducted the loan repayment and credited the remaining proceeds to the farmers' savings accounts. This deduction of the proceeds for loan repayment essentially allows MRFC to "seize" the paprika crop when farmers sell to CP (and for most farmers it is the only sales outlet). Researchers used data on loan sizes and repayment timing and rates to measure the impact of the fingerprinting program.

THE CHALLENGE OF LENDING IN AGRICULTURAL SETTINGS

Lending is particularly difficult in agricultural settings because the nature of agricultural production complicates the use of many common microfinance mechanisms. For example, lenders cannot schedule frequent repayments because farmers receive cash flows from their investments only after the harvest, several months after the loan is taken. Additionally, all farmers need cash at the same time to purchase inputs, so allowing some farmers to borrow only after others have repaid their loans would mean that some farmers would end up receiving credit when they do not need it. Joint liability models may also be ineffective if all farmers in one area are subject to the same production shocks, such as floods or droughts.

Lending is further complicated in settings such as Malawi that lack a national identification system. In the absence of fingerprinting, identification of borrowers relies on the personal knowledge of loan officers. But at MRFC, loan officers transfer branches about every two years, and thus area-specific institutional memory is lost. Even when officers are not transferred, it is easy to see how mistakes in identifying individual borrowers could be made: MRFC's 120 credit officers handle upwards of 50,000 loans per year. This difficulty in tracking identity opens the door for past defaulters to take out new loans under false identities, which creates an obstacle for MRFC and other lenders to expand access to credit.

Farmers were not deterred from taking out loans. A concern might be that famers would oppose being fingerprinted, if they, for example, associate fingerprinting with the criminal justice process. In this case, fingerprinting might reduce access to credit for farmers who simply did not want to be fingerprinted. However, in Malawi, fingerprinting did not reduce the likelihood that a farmer would take out a loan, and the researchers did not encounter any resistance from the farmers who were fingerprinted, perhaps because it was a novel technology.

Among the farmers who took out loans, the fingerprinted borrowers chose smaller loans. On average, fingerprinted borrowers took out loans that were MWK 693 (approximately US$5) smaller than borrowers in the comparison group. This effect is mostly driven by the subset of borrowers with the highest default risk, based on a "predicted repayment" measure the researchers constructed from individual characteristics in the baseline survey. This result suggests that farmers predicted to be high-risk borrowers made the choice to take out smaller, less risky loans when they knew they could be identified in the future.
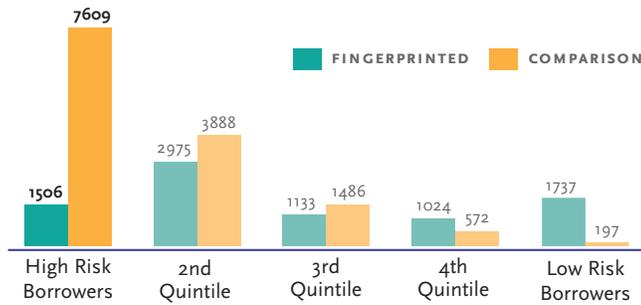

Fingerprinting led farmers to allocate more land and farming inputs to paprika, the crop with which loans were repaid. One way a farmer could default on the loan would be to divert the subsidized inputs intended for paprika to other crops, while neglecting the paprika crop and allocating little land to grow it. The farmer could then sell the other crops, while leaving Cheetah Paprika with a paprika harvest too small to recover the costs of the borrowed input package.

Researchers find that fingerprinting led farmers with the highest risk of default to allocate about 8 percentage points more land to paprika, a result that is marginally statistically significant but meaningful in magnitude, as it leads to a nearly 50 percent increase in the amount of land devoted to this crop. In the long run, the effect on land allocated to repayment crops could be even greater, since in this case farmers began preparing and allocating land before the introduction of fingerprinting.

The results suggest that fingerprinted farmers in the high-risk group used more paid inputs in total on the paprika crop relative to comparison farmers in the same group. There is also evidence that fingerprinting made farmers less likely to dispose of subsidized inputs via sale or barter.

RESULTS

FIGURE 1:
UNPAID BALANCE (MWK) 2 MONTHS AFTER LOAN WAS DUE
STATISTICALLY SIGNIFICANT DIFFERENCES ARE BOLD

Fingerprinting improved loan repayment, particularly for borrowers expected to have the poorest repayment performance. Two months after the loan was due, fingerprinted borrowers predicted to be high-risk had much lower outstanding loan balances than their peers in the comparison group. (See the first set of bars in Figure 1.)
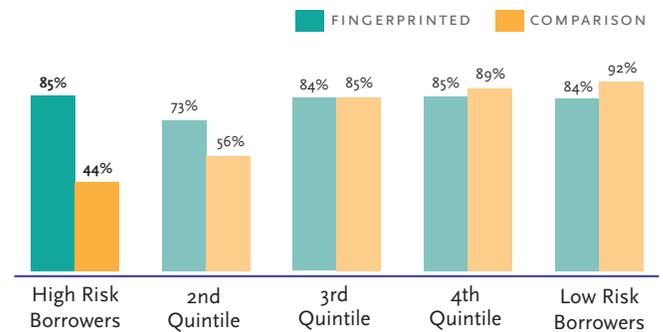

BIOMETRIC TECHNOLOGY

Common biometrics used for personal identification include a person's fingerprints; face, iris or retina patterns; speech; or handwritten signature. These are effective personal identifiers because they are unique and intrinsic to each person, and unlike conventional identification methods (such as a passport number or government-issued identification cards), they cannot be lost, forgotten, or stolen.

Recent advances in biometric recognition technology have made the use of biometrics (such as fingerprints) feasible in an increasing number of contexts. For example, in the developing world, biometric identification systems are being used to improve the effectiveness of targeted government programs which require unique identification of beneficiaries, such as those being used in India. Fingerprinting technology is also being used in Malawi and other countries in place of PINs to allow people to access their bank accounts at ATMs.

While outstanding balances should be mechanically lower due to high-risk borrowers taking out smaller loans, the effect is almost three times as large as the reduction in loan size, so the fact that farmers had smaller loans to repay cannot alone explain this increase in repayment rates.

Additionally, for borrowers in the highest-risk group, the average share of the loan amount repaid two months after the due date was 92 percent among fingerprinted borrowers, relative to 67 percent in the comparison group. In other words, for these farmers, fingerprinting closes roughly three-quarters of the gap between repayment rates in the comparison group and full repayment. Fingerprinting also nearly doubled the proportion of highest-risk borrowers who fully repaid their loan on time, and who fully repaid their loan eventually (Figure 2). By contrast, farmers in the low-risk groups did not change their repayment rates in response to fingerprinting.

FIGURE 2:
PROPORTION OF BORROWERS WHO FULLY REPAY THEIR LOANS
STATISTICALLY SIGNIFICANT DIFFERENCES ARE BOLD

Using biometric technology to identify borrowers had a high rate of return for the lender. The researchers conservatively estimate a net benefit to the lender of MWK 281 (US$1.94) per individual fingerprinted, and a benefit-cost ratio of 2.34, based on benefits to the lender in terms of increases in repayment, and costs including equipment, loan officer time, and transaction costs per fingerprint checked. There may also be other benefits to the lender that this ratio does not capture. For instance, the impact of fingerprinting may become larger over time as the lender's dynamic incentives become more credible.

See Tables 3 and 4 in Giné, Goldberg and Yang (2011) for full regression-adjusted results.

POLICY LESSONS

Personal identification can significantly improve client repayment rates and therefore improve credit market efficiency. Borrowers, especially high-risk borrowers, responded strongly to knowing that they could be easily identified by lenders in the future. Risky borrowers voluntarily chose smaller loans in order to improve their likelihood of repayment (reducing adverse selection) and devoted more land and agricultural inputs to the crop with which the loan was repaid (reducing moral hazard). In economic terms, this reduced information asymmetries and improved the efficiency of the credit market through improved repayment rates.

Improved identification may address one barrier to providing credit in rural areas. If difficulty in identifying borrowers deters lenders from offering credit, the fingerprinting techniques explored in this evaluation could potentially reduce one of the risks of providing credit in rural areas. Further research could explore whether improved identification systems would make lenders more likely to increase the supply of credit or offer more favorable borrowing contracts to well-performing borrowers.

Borrower responses to personal identification systems offer lessons for establishing credit bureaus. Although Malawi does not have a national credit bureau, study participants were told that their fingerprints and credit histories could be shared with other lenders. The results indicate that borrowers, and particularly the riskiest borrowers, do change their repayment behavior when they believe that improved identification will allow lenders to condition credit decisions on past credit performance. While this study operated in a very specific context, its results can provide clues for how borrowers may respond to identification systems that allow lenders to share credit histories through a credit bureau.
